Abstract— Cloud computing is a large model change of computing system. It provides high scalability and flexibility among an assortment of on-demand services. To improve the performance of the multi-cloud environment in distributed application might require less energy efficiency and minimal inter-node latency correspondingly. The major problem is that the energy efficiency of the cloud computing data center is less if the number of server is low, else it increases. To overcome the energy efficiency and network latency problem a novel energy-efficient particle swarm optimization representation for multi-job scheduling and Latency representation for the grouping of nodes with respect to network latency is proposed. The scheduling procedure is through on the basis of network latency and energy efficiency. Scheduling schema is the main part of Cloud Scheduler component, which helps the scheduler in scheduling decision on the base of dissimilar criterion. It also works well with incomplete latency information and performs intelligent grouping on the basis of both network latency and energy efficiency. Design a realistic particle swarm optimization algorithm for the cloud servers and construct an overall energy competence based on the purpose of the servers and calculation of fitness value for each cloud servers. Also, in order to speed up the convergent speed and improve the probing aptitude of our algorithm, a local search operative is introduced. Finally, the experiment demonstrates that the proposed algorithm is effectual and well-organized.

Index Terms— Cloud Computing, Network Latency, Energy Efficiency, Particle Swarm Optimization (PSO) and Multi-Job Scheduling

I. INTRODUCTION

Cloud computing becomes a one of important rising and an empowering technology in now a days, because which through us to consider beyond what is possible. These technologies related services are offered by general 3-tier architecture. The complete architecture of the cloud technology performed based on the user request to service the requirements or perform scheduling based on user required task or job. In order to perform scheduling strategy it incorporates of the resource provider, the service

Providers and the consumers are the Service provider requires particular new hardware resources or resource provider to perform service request given by the user. It becomes the one of the technology [1] for empowering well-situated, on-demand network admission to a public collection of specific cloud computing resources, that can be quickly provisioned and delivered with less organization effort. As a new business model, though an individual privileged are provided by that services such as on-demand self-service, wide network access, and quick flexibility. Cloud computing faces a number of new challenges. One of the well-known challenges is the energy efficiency of cloud servers or data centers.

If an appliance requires organization between dissimilar cloud nodes, then the performance of cloud technology degraded due to the network latency, elevated inter-node latency. Thus presents a high demand to contain the inter-node latency as smallest as probable. In order to enclose a solution for this situation must include a collection of nodes which have less inter-node latency and also have the minimal number of nodes necessary for the application. Necessary a precise method, which is mainly valuable for distributed application, which desire to run on numerous nodes and have smallest amount probable inter-node latency. According to the current CEMS project from amazon’s [2], amortization schedule for 3-years and amortization schedule for 15 -years are crosspodingly used for servers. In other words, the largest speculation to construct data centers for cloud computing is not simply to obtain millions of server equipment, but also to acquire the distribution and cooling infrastructure and to compensate the bill for energy utilization of every one of these facilities.

In order to solve that problem such as network latency and energy efficiency, a technique called latency and particle swarm optimization based energy-efficient multi-job scheduling is proposed to supports both the problems. This effort mostly focuses on how to develop the energy efficiency and decrease the network latency of servers during suitable scheduling strategies.

Taking complete concern of the association among the performance and energy utilization of servers, network latency for energy efficiency proposes a new particle swarm optimization based energy-efficient multi-job scheduling model based on the cloud environment, MapReduce and give its equivalent particle swarm
optimization algorithm. Latency based is used, to model for grouping the nodes with smallest inter-node latency together. This algorithm fulfills all the necessities mentioned in the problem statement. The network latency algorithm is moderately able to group the nodes with the less obtainable latency information and make equally selected groups with negligible communication overhead with less energy efficiency in cloud environment. But, the requirement’s in the existing methods that does not satisfy in one or more condition. But none of them fulfills all of the requirements. Proposed work fulfills all the requirements as mentioned above. The whole work of the paper is organized as below the section 2 study the network latency and energy efficiency problem related methods, section 3 latency and particle swarm optimization based energy-efficient multi-job scheduling for group discovery algorithm, section 4 experimental results were measured and finally section 5 concludes the result.

II. RELATED WORK

Clustering or grouping of the nodes in the cloud environment has a several characteristics is referred to as community detection. Community, group, or cluster detection comprise be completed for various areas and fields, together with internet [3], WWW [4], biological network [5], extract network [6], graph theory [7] and so on. Dissimlar algorithms have been proposed to modify to the requirements of the regulation. The majority of these algorithms are based on grouping of nodes on the foundation of association calculation for an exacting node.

Resource Aware Cloud computing framework (RAC2) [8] and the accomplishment of its algorithm is constituent of the Resource Awareness Cloud Scheduling (RACS) constituent. RACS component assist the scheduler in the creation more of well-organized scheduling decisions on the foundation of dissimilar resource characteristics/criterion. Network latency becomes one of those criterions. With the assist of cloud resource manager, RACS has information regarding the numeral number of nodes obtainable from dissimilar cloud operator and community detection.

Due to the advance development of cloud service provider technology, an organization has to choose variety of cloud operators. But it becomes actually complicated to choose one cloud operator, as better than the other cloud operators within the same cloud services and lacking following in various other services and attributes. NACS module assists the scheduler in responsibility, this significant choice of nodes assortment. For carrying out tests rationale, have plugged in our scheduler section with ProActive scheduler [3]. ProActive is an open source cloud middle-ware, which enables the consumer to accomplish its tasks on a group or cloud infrastructure.

Anderson et al. [9] developed a Local spectral partitioning algorithm for partitioning the cloud operations. It is one of the types of graph partitioning algorithm and it use page rank vector to attain its partitioning procedure for operators. They expected to decrease the conductance in their algorithm. It can cluster the nodes on the beginning of connection assessment and generate equally restricted groups. It also does not necessitate an algorithm to run every time, whenever you like a procedure demands for a cluster.

Lang et al. [10] also presented a graph partitioning algorithm Flow-based Metis+MQI. The main aim of the algorithm is to increase the conductance of graph cuts. They have shared MQI with Metis to achieve a heuristic graph partitioner to discover the outcome. It can cluster the nodes on the beginning of connection value and construct equally restricted groups. Similar to Local Spectral, it furthermore does not necessitate the algorithm to run every time, every time a procedure demands for a cluster.

Garcia et al. [11] presented a Hierarchical compact algorithm and hierarchical star algorithm for measuring the group nodes collection; it is based on universal structure for agglomerative hierarchical clustering. In which they experienced and compared these algorithms. The structure is based on graphs. They attain the dissimilar hierarchical agglomerative clustering algorithms starting this structure by using dissimilar measures. They measured the result of these algorithms using the normal document collections. The structure does not work well on each and every node of connection value, it also does not generate equally restricted groups with additional time complication.

To decrease the energy utilization of data centers and recover energy efficiency, numerous scholars have completed a number of associated researches, such as literatures [12-16]. Decrease energy addicted by cooling scheme. For instance, you preserve to use Google’s “free cooling” approach, heat of each servers from free cooling mode are removed by using low heat ambient air.

Google states that still there is no specific cooling equipment available for data centers in Belgium [17]. According to the success of google engineers, the climatic conditions of the belgium support free cooling approximately year-round, with temperatures increasing higher than the suitable assortment for free cooling concerning seven days per year. Improve the energy efficiency of servers are responsive with the aim of low energy consumption of a server is mostly outstanding to its idle status caused by low CPU consumption.

Even at an extremely low load CPU upto ten percentage (10%) CPU utilization, the power addicted is greater than half of the percentage (50%) of the peak power [18]. Thus, the energy effectiveness of servers plays a significant responsibility for the complete energy efficiency of the data center.

III. LATENCY AND PARTICLE SWARM OPTIMIZATION BASED ENERGY-EFFICIENT MULTI-JOB SCHEDULING FOR GROUP DISCOVERY ALGORITHM
In existing network latency grouping algorithm doesn’t add the energy efficiency conception in all stages of group discovery algorithm, so it becomes more energy consumption with less network latency to overcome the problem, a proposed work tradeoff among energy consumption and network latency for group discovery algorithm. The basics of the proposed work are grouping the similar nodes with less inter-node latency and less energy utilization for every service provider (SP). In the initial stage of cloud scheduler, it makes the decision for scheduling based on the grouping information obtained from network latency and PSO based energy efficiency multi-job scheduling algorithm. In this resolution, it is reasonably proficient to cluster the nodes with the smallest obtainable latency and energy information results from PSOBEMJS ( ). Latency and energy information is accessible only for those nodes, which comprise done several communications through other nodes. Thus the sensible result of which heuristically performs the combination decision on incomplete latency and energy information. For network latency this work does not depend on broadcasting schema to evaluate the inter-node latency, since these schemas consumes larger energy with high bandwidth and put a burden on network traffic. It does not send a message to neighbour nodes or other nodes to evaluate the network latency, to evaluate the network latency for the nodes with the same communication by using piggy back technique.

The algorithm runs for each and every time to find the less network latency and minimum energy efficiency also evaluated using multi job scheduling algorithm in same intilization phase. This latency and energy efficiency is compared to a threshold, PMU and group threshold value, for making the decision to group the similar nodes. The iteration of the algorithm is performed when it equals to the number of nodes with number of times. The algorithm has three dissimilar phases; initialization, configuration and reconfiguration. Initialization phase is dependable to place the situation for the algorithm implementation. Configuration phase is dependable to find out the groups, it is the major core part of the phase. In detail it is the concrete group discovery phase. Final phase of the algorithm is Reconfiguration phase. It groups the nodes which are not grouped with other nodes in the configuration phase. Before going more into the details of these phases, first introduce the energy efficiency algorithm that are going to be used in group discovery algorithm.

Improving the energy effectiveness of cloud servers, the Power usage effectiveness (PUE) of data centers can be improved. Though, this energy utilization problem cannot be easily solved by using general load balancing between the servers consequently while to formulate all the servers CPU utilization as an alternative, there exists an best performance and energy peak for each server [18]. Energy utilization per task is inclined by the CPU consumption of servers other than, in order to make simpler the representation, simply consider the impact of CPU utilization. While the CPU utilization is small, power of each server is not mentioned effectively and therefore the energy efficiency for each task is high. In other hand while the CPU utilization is high as well as the energy utilization of each server is high, due to the contest for resources between tasks, it leads to degradation of performance and more execution time per task. In previous work the variation of energy for each task is measured by using “U-shaped” curve with CPU utilization. So it can be understood that the servers accomplish the optimal energy efficiency when all servers consecutively at its best possible performance. Get this best optimal result of energy efficiency for each server, first give the major work related description of the energy-efficient multi-job scheduling difficulty and then build its matching particle swarm optimization (PSO) algorithm.

The scheduling procedure of the algorithm considers the N servers for each data center. Consider the present utilization of the CPU resources for each server k is denoted as CS_k and its best optimal values of CPU utilization are CO_k, where k = 1, 2, .... N. If there are J jobs to perform for each cloud server A = \{A_1, .... A_J\} necessitate being process and the input server data for each job A_q is D_q where q = 1, 2, .... J. The input data file of each and every cloud server data D_q determination is separated into m_q equal splits with each size, consequently present be \(\bar{m} = \sum_{q=1}^{J} m_q\) splits, which are denoted as in the equation \(s D = \{D_1, D_2, ... , D_J\} = \{d_{i1}, d_{i2}, ... , d_{im}\}.\) It first required storing the result of each splits on N servers. To make sure the consistency of data, every split might select combination of three dissimilar servers for each and every storage node. Using a \(\bar{m} \times 3\) matrix P to correspond to the storage space position of each split, and the constituent p_{ij} indicates the storage space position of split d_i, somewhere integer integer p_{ij} \in [1,N], i = 1, 2, .... \bar{m} denoted the nodes and j = 1, 2, 3 ....the corresponds to the MapReduce structure, know that every input data D_q determination to be procedure by map and reduce process, it is represented as m_q and r_q with less CPU utilization for map and reduce process, it is also represented as CM_q and CR_q.

The major difficulty of the process is how to assign the job to each and every split of data center for N server with less energy efficiency, for that purpose need to convert the map and reduce task data into vector form of representation that is \(v = \sum_{q=1}^{J} m_q + \sum_{q=1}^{J} r_q\). The vector representation of data center is converted into scheduling task with current node and NeighborNode \(S = (s_1, s_2, ... , s_i, ... , s_v)\) to represent the completed task of scheduling procedure, and the ith constituent of vector S indicate that task i is assigned on server s_i where \(1 \leq s_i \leq N\) and i = 1, 2, .... , v . Traversing throughout the scheduling process S and achieve the set of map and reduce results for each and every job A_q which are assigned on server k, it is denoted as MM_{sk} and NR_{sk}, correspondingly, where \(k = 1, 2, ... N\) and \(q = 1, 2, ... J\) Let \(NM_{sk}^k = |M_{sk}^k|\) and \(NR_{sk}^q = |R_{sk}^q|\). Here give the PSO optimization model for the multi-job scheduling
difficulty with energy efficiency based on MapReduce structure for cloud computing:

\[
\min \sum_{k=1}^{N} \left( C_{K} + \sum_{q=1}^{F} (NM_{K}^{q} \times CM_{q}) + \sum_{q=1}^{F} (NR_{K}^{q} \times CR_{q}) \right)^{2}
\]  

(1)

satisfies that for scheduling schema S,

\[
\begin{align*}
& s_{i} \in [p_{i1}, p_{i2}, p_{i3}] \quad \text{for } i = 1, 2, \ldots, m \\
& s_{i} \in [1, N] \quad \text{for } i = m + 1, m + 2, \ldots, v
\end{align*}
\]  

(2)

\[
NM_{K}^{q} = \left\{ \begin{array}{l}
s_{i} = k, i \\
= m + 1, m + 2, \ldots, v
\end{array} \right\}
\]

\[
= \sum_{j=0}^{q-1} m_{j} + 1, \sum_{j=0}^{q-1} m_{j} + 2, \ldots, \sum_{j=0}^{q-1} m_{j} + m_{q}
\]

\[
+ m_{q} \right\}
\]  

(3)

where \( m_{o} = 0, k = 1, 2, \ldots, N, q = 1, 2, \ldots, F \)

\[
NR_{K}^{q} = \left\{ \begin{array}{l}
s_{i} = k, i \\
= m + 1, m + 2, \ldots, v
\end{array} \right\}
\]  

\[
= \sum_{j=0}^{q-1} m_{j} + 1, \sum_{j=0}^{q-1} m_{j} + 2, \ldots, \sum_{j=0}^{q-1} m_{j} + m_{q}
\]

\[
+ m_{q} \right\}
\]  

(4)

where \( r_{o} = 0, k = 1, 2, \ldots, N, q = 1, 2, \ldots, F \)

\[
CS_{K} + \sum_{q=1}^{F} (NM_{K}^{q} \times CM_{q}) + \sum_{q=1}^{F} (NR_{K}^{q} \times CR_{q}) \leq 1
\]  

(5)

where \( k = 1, 2, \ldots, N, CM_{q} \in [0, 1], q = 1, 2, \ldots, F \)

The objective function of the PSO algorithm needs to calculate the CPU utilization after scheduling and their optimal points. Equation (2) express to facilitate if there is map tasks \( s_{i} \) is assigned to server \( s_{i} \) and then stores the corresponding data of this map task \( s_{i} \). This is because the MapReduce structure is mostly used in enormous data dispensation and the network bandwidth is a comparatively limited resource requirement in cloud computing environment. MapReduce prefers affecting the decision-making group discovery algorithm to the corresponding node which stores the data, other than moving the data as in conventional distributed computing. These types of scheduling schema avoid a large-scale data progress by not only reducing the bandwidth, but also map and process the data in efficient manner. Equation (3) and (4) compute the number of map tasks \( NM_{K}^{q} \) and reduce tasks \( NR_{K}^{q} \) of job \( A_{q} \) which are assigned to server \( k \). Equation (5) denotes to utilization of CPU for any server must not go beyond earlier than and following the task scheduling.

A particle swarm optimization (PSO) is the general comparable to a behaviour of fish or bird moving in dimensional search or investigation search space. Bases on the individuality of this energy efficient problem, agree to the integer coding, convert the map and reduce task data into vector form of representation that is \( v = \sum_{q=1}^{F} m_{q} + \sum_{q=1}^{F} r_{q} \) including \( m = \sum_{q=1}^{F} m_{q} \) map tasks and \( r = \sum_{q=1}^{F} r_{q} \) reduce tasks. The initialization of every one particle is the to consider the tasks to be scheduled with vector \( S = (s_{1}, \ldots, s_{v}) \) as an individual to represent a scheduling scheme \( S \) indicate that task \( k_{i} \) is assigned on servers \( i \). All particles have fitness values demonstrating their performances of each and every server \( K \) and velocities which straight the journey of particles. Equation (1) represents each particle location of each server energy efficiency best values are inclined by together both local and global best energy efficiency optimal results, it is referred to as pbest. If pbest. Therefore particles have a tendency to fly towards an improved best energy efficiency exploration area throughout the search procedure. A particle position on the search freedom is specified by two basics, namely its velocity and position, which are updated in each and every generation as follows:

**Procedure 1: Energy efficiency particle swarm optimization based energy-efficient multi-job scheduling algorithm PSOEBMJS ( )**

**Step 1:** Initializing the particles with scheduling vector \( S = (s_{1}, \ldots, s_{v}) \) and mapreduce functions \( NR_{K}^{q} \) and \( NM_{K}^{q} \) let \( NM_{K}^{q} = 0 \) and \( NR_{K}^{q} = 0 \) where \( k = 1, 2, \ldots, N \) and \( q = 1, 2, \ldots, q \) empty set \( M_{K} \) and \( R_{K} \).

**Step 2:** For \( i = 1, 2, \ldots, N \) where \( N \) is the size of the particles that corresponds to the scheduling vector. For each element \( s_{i} \) of individual \( S \) set \( k = s_{i} \) and \( m_{o} = 0 \).

**Step 3:** For a job \( A_{q} \) where \( q = 1, 2, \ldots, J \)

3.1. If \( i = \sum_{j=0}^{q-1} m_{j} + 1, \sum_{j=0}^{q-1} m_{j} + 2, \ldots, \sum_{j=0}^{q-1} m_{j} + m_{q} \), \( NR_{K}^{q} \) plus one and put \( i \) into set \( M_{K} \)

3.2. Else

3.3. If \( i = \sum_{j=0}^{q-1} r_{j} + 1, \sum_{j=0}^{q-1} r_{j} + 2, \ldots, \sum_{j=0}^{q-1} r_{j} + r_{q} \), \( NR_{K}^{q} \) plus one and put \( i \) into set \( R_{K} \).

**Step 4:** For \( j = 1, 2, \ldots, K \) where \( k \) is the number of servers and randomly initializes frequency to the servers.

**Step 5:** Initialize a population of particles with random positions and velocities \( V[i] \) in the search space.

**Step 6:** Initialize the local best energy efficiency as pBest of each scheduling vector \( pBest[i] = S_{i} \).

**Step 7:** Evaluate objectives of each particle using the (2), (3), (4), (5).
Step 8: Initialize the Global Best particle (gBest) with the best one among N the particles: gBest = Best particle found in S
Step 9: End For
Step 10: Add the no dominated solutions found in S into objective function in step (7)

**Procedure definition:**

Initialize:

```
CheckForGroupableToVisitNodeRoot (VisitNode, NeighborNode),
CheckForEnergyEfficiency(VisitNode, NeighborNode) from PSOBEEMJS() if sumOfLatency(neighborOfVisitNode, rootOfVisitNode) > groupThreshold and sumOfEnergyEfficiency(neighborOfVisitNode, rootOfVisitNode) < PUE then increase moreThanGroupThresholdCounter end
```

Step 11: Initialize the iteration number t = 0

**Step 12:** Repeat until t > G (G is the maximum number of iterations)

1. For i = 1, 2, ..., N
2. Randomly select the global best particle for Si from the map reduce vector v store its position in gBest.
3. Calculate the new velocity Vi according to following equation
   \[ V_{i}^{k+1} = \alpha V_{i}^{k} + c_{1}r_{1}(p_{best_{i}} - S_{i}^{k}) + c_{2}r_{2}(g_{best} - S_{i}^{k}) \]
   \[ S_{i}^{k+1} = S_{i}^{k} + V_{i}^{k+1} \]
4. Compute the new velocity of Si according to following equation
   \[ V_{i}^{k+1} = V_{i}^{k} + ((R_{1} \ominus p_{best_{i}} \ominus S_{i}^{k} \ominus R_{2} \ominus g_{best} \ominus S_{i}^{k}) S_{i}^{k+1} = S_{i}^{k} + V_{i}^{k+1} \]
5. If (t < G * PUE) then (PUE is the Power usage effectiveness) Perform mutation on Si

**Step 13:**

1. For each neighbourNode of visitNode do
   1. input latency(visitNode, neighborNode), energy(visitNode, neighborNode)
   2. If latency(visitNode, neighborNode) ≤ threshold & energyEfficiency(visitNode, neighborNode) ≤ PMU then
      1. add neighborNode into tempGroup
      2. call_proc: checkForGroupableToVisitNodeRoot (visitNode, neighborNode)
      3. call_proc: CheckForEnergyEfficiency(VisitNode, NeighborNode) from PSOBEEMJS() end
      4. add neighborNode to newGroup
      5. end
   3. end
   4. end
 5. end

**Step 14:** Find best Si

1. End For

**Step 15:** Update the global best solution of each particle Si

1. If Si ≤ pbesti ∨ Si ~ pbests then Then pbesti = Si update current solution

**Step 16:** Add non relevant scheduling task to reduce Rk

1. If S1 ≠ x ∀ x ∈ S Then S = S ∪ S1

**Step 17:** Remove all particles dominated by Si in S

1. S = S - {y ∈ S | Y < S1}

**Step 20:** If the archive is full then randomly select the article to be replaced from map reduce with scheduling task S with respect to NRPk and NMk

1. If the stopping criterion is met step 12, then output gBest and its objective value; otherwise, go to Step (6)

**Step 23:** Return the best result

Power usage effectiveness (PUE) is used to evaluate the energy efficiency of each data and it is the ration of sum of all power used by data center delivered to cloud computing equipment. It is to determine of how professionally a processor data center use its power:

\[ \text{PUE} = \frac{\text{Total facility number}}{\text{IT equipment power}} \]

Then now proceed how the energy efficiency concept is performed for each and every phase of the group discovery algorithm both energy efficiency and network latency. The procedure of these three phases as follows:

**A. Initialization:**

**B. Group Discovery Algorithm -- Configuration Phase:**

**Data:** nodes, latency, threshold, groupThreshold, energyEfficiency, PMU

**Result:** Groups of Nodes with minimal inter-node latency and less energy efficiency

**Initialization:**

```
for each node in registry do
  select visitNode
  If numberOfneighborOfVisitNode = 0 OR ( previousOfVisitNode = null & visitnode ≠ grouped ) then
    create newGroup
    add visitNode to newGroup
    end
  for each neighbourNode of visitNode do
    input latency(visitNode, neighborNode), energy(visitNode, neighborNode)
    If latency(visitNode, neighborNode) ≤ threshold & energyEfficiency(visitNode, neighborNode) ≤ PMU then
      add neighborNode into tempGroup
      call_proc: checkForGroupableToVisitNodeRoot (visitNode, neighborNode)
      call_proc: CheckForEnergyEfficiency(VisitNode, NeighborNode) from PSOBEEMJS() end
      add neighborNode to newGroup
      end
    end
  end
  check that the tempGroup is group table to groupOfRootNode or not
```

Copyright © 2014 MECS I.J. Information Technology and Computer Science, 2014, 10, 48-55
if morethanGroupThersholdCounter ≤ regroupingIndex then
    copy tempGroup to groupOfVisitNode
else if ThersholdCounter > regroupingIndex then
    create newGroup
if isVisitNodeRemovable = true then
    add visitNode to newGroup
end
end

C. Group Discovery Algorithm—Reconfiguration Phase:

Data: nodes, groups, latency, threshold, pairLatency, prevMinLatency, PMU, Energy efficiency

Result: Groups of Nodes with minimal inter-node latency and less energy efficiency

Initialization:

for each group in registry do
    PrevMinLatency ← 0, PMU ← 0
    if groupSize = 1 then
        for each potentialGroup in registry do
            if potentialGroupSize > 1 then
                pairLatency ← findPairLatency(currentNode, potentialGroupLeader)
            end
            if pairLatency ≤ threshold and (pairLatency < prevMinLatency or prevMinLatency = 0) then
                prevMinLatency ← pairLatency
                prevMinPMU ← taskenergy
            end
        end
    end
end

move candidateNode to newGroup
newGroupNumber ← potentialGroup
end
end
update latency and energy efficiency in registry

Energy-Efficient PSO and Latency Based Group Discovery Algorithm in Cloud Scheduling

V. CONCLUSION AND FUTURE WORK

The energy efficiency of the each and every cloud plays a major important role to improve the overall energy utilization. This paper majorly focuses on how to reduce the energy utilization of cloud servers throughout suitable scheduling schema. Taking full contemplation of the association among the result of cloud server with less network latency and less energy utilization of servers, propose a novel network latency and energy-efficient particle swarm optimization based multi-job scheduling representation based on the data processing structure, MapReduce, and give the equivalent algorithm. And also proposed a Particle Swarm Optimization (PSO) method for scheduling the tasks and which also improve the energy efficiency by finding the fitness value of the particles. It specially target the state when do not contain entire information concerning all the inter-node latencies and energy efficient information from PSOBEEMJS algorithm. The proposed system provides a possible solution for grouping of nodes with respect towards their inter-node latency and less energy efficiency.

Proposed optimization based workflow scheduling in cloud computing is not a full-grown field. Most of the obtainable mechanism efforts reduce either the make span or cost only. Though, in future work will map to believe additional objectives such as dependability, protection in adding together to the energy utilization mean to apply our algorithm in the real cloud.
